Edited by B. Clark Burchfiel, Massachusetts Institute of Technology, Cambridge, MA, and approved March 29, 2012 (received for review October 19, 2011)

Cenozoic convergence between the Indian and Asian plates produced the archetypical continental collision zone comprising the Himalaya mountain belt and the Tibetan Plateau. How and where India–Asia convergence was accommodated after collision at or before 52 Ma remains a long-standing controversy. Since 52 Ma, the two plates have converged up to 3,600 ± 35 km, yet the upper crustal shortening documented from the geological record of Asia and the Himalaya is up to approximately 2,350-km less. Here we show that the discrepancy between the convergence and the shortening can be explained by subduction of highly extended continental and oceanic Indian lithosphere within the Himalaya between approximately 50 and 25 Ma. Paleomagnetic data show that this extended continental and oceanic “Greater India” promontory resulted from 2,675 ± 700 km of North–South extension between 120 and 70 Ma, accommodated between the Tibetan Himalaya and cratonic India. We suggest that the approximately 50 Ma “India”–Asia collision was a collision of a Tibetan-Himalayan microcontinent with Asia, followed by subduction of the large Asian Greater India Basin along a subduction zone at the location of the Greater Himalaya. The “hard” India–Asia collision with thicker and contiguous Indian continental lithosphere occurred around 25–20 Ma. This hard collision is coincident with far-field deformation in central Asia and rapid exhumation of Greater Himalaya crystalline rocks, and may be linked to intensification of the Asian monsoon system. This two-stage collision between India and Asia is also reflected in the deep mantle remnants of subduction imaged with seismic tomography.

The present geological boundary between India and Asia is marked by the Indus–Yarlung suture zone, which contains deformed remnants of the ancient Neotethys Ocean (1, 2) (Fig. 1). North of the Indus–Yarlung suture is the southernmost continental fragment of Asia, the Lhasa block. South of the suture lies the Himalaya, composed of (meta)sedimentary rocks that were scraped off now-subducted Indian continental crust and mantle lithosphere and thrust southward over India during collision. The highest structural unit of the Himalaya is overlain by fragments of oceanic lithosphere (ophiolites).

We apply the common term Greater India to refer to the part of the Indian plate that has been subducted underneath Tibet since the onset of Cenozoic continental collision. A 52 Ma minimum age of collision between northernmost Greater India and the Lhasa block is constrained by 52 Ma sedimentary rocks in the northern, “Tibetan” Himalaya that include detritus from the Lhasa block (3). This collision age is consistent with independent paleomagnetic evidence for overlapping paleolatitudes for the Tibetan Himalaya and the Lhasa blocks at 48.6 ± 6.2 Ma (Fig. 2; SI Text) as well as with an abrupt decrease in India–Asia convergence rates beginning at 55–50 Ma, as demonstrated by India–Asia plate circuits (e.g., ref. 4). Structural (5) and stratigraphic (6) data show that ophiolites were emplaced over the Tibetan Himalaya in the latest Cretaceous (approximately 70–65 Ma), well before the Tibetan Himalaya–Lhasa collision. Paleomagnetic data suggest that these ophiolites formed at equatorial paleolatitudes (7).

Motion between continents that border the modern oceans is quantified through time using plate reconstructions based on marine magnetic anomalies. The Eurasia–North America–Africa India plate circuit demonstrates 2,860 ± 30 and 3,600 ± 35 km of post-52 Ma India–Asia convergence for the western and eastern Himalayan syntaxes, respectively (4). It has long been recognized that the amount of upper crustal shortening since 52 Ma reconstructed from the geology of the Himalaya and Asia accounts for only approximately 30–50% of this total convergence (8) (Fig. 1). Previously proposed solutions for this “shortening deficit” include major unrecognized shortening in Siberia (8, 9), a >1,000-km eastward extrusion of Indochina from an original position within Tibet that would lead to >2,000 km of Cenozoic intra-Asian shortening (10–12), or a much younger Tibetan Himalaya–Lhasa collision (13). However, geologically reconstructed shortening of approximately 1,050–600 km (from west to east) within and north of the Pamir and the Tibetan plateau without invoking major Indochina extrusion (14) is consistent with 1,100 ± 500 km of paleomagnetically constrained convergence between the Indus–Yarlung suture and Eurasia since approximately 50 Ma (15). The excess convergence should therefore mostly have been accommodated in the Himalaya, to the south of the Indus–Yarlung suture.

The Himalaya consists of upper continental crust that was decoupled from now-subducted Greater India (1, 2), which is generally considered to have formed the contiguous margin of northern India (2, 16–18). The Himalaya is divided into three tectonostratigraphic zones (Fig. 1). From north to south, these include the non- to low-metamorphic grade sedimentary rocks of the Tibetan Himalaya, separated by the South Tibetan detachment from the igneous and high-grade metamorphic Greater Himalaya, which overlies the low-grade, internally thrusted Lesser Himalaya along the Main Central thrust (1, 2) (Fig. 1).

The authors declare no conflict of interest.

Comprehensive balanced cross-sections across the Himalaya documented approximately 500–900 km of shortening (19, 20). These estimates are the sum of (i) shortening in the Tibetan Himalaya (since the Paleogene); (ii) the amount of overlap between the Greater Himalaya and the Lesser Himalaya along the Main Central thrust that was largely established between approximately 25–20 and 15–10 Ma; and (iii) the amount of shortening within the Lesser Himalaya since approximately 15–10 Ma (2, 19, 20). The main uncertainty in the Himalayan shortening estimates is associated with the Greater Himalaya. Intense Miocene deformation has effectively overprinted any older structures in the Greater Himalaya, but well-dated prograde mineral growth and magnetism in the Greater Himalaya shows evidence for burial and heating between 45 and 25 Ma (21–23). The amount of shortening accommodated within or below the Greater Himalaya prior to the Miocene therefore remains geologically unconstrained, but could be considerable. Detrital zircon studies of the Lesser, Greater, and Tibetan Himalaya suggest that their Neoproterozoic to lower Paleozoic (Cambrian-Ordovician) stratigraphies are similar (16, 24–26), suggesting that the net effect of post-Ordovician tectonics within the Himalaya was limited to perhaps several hundreds of kilometers of shortening.

The amount of India–Asia convergence since 52 Ma (up to 3,600 ± 35 km, ref. 4) exceeds the estimated total crustal shortening within Asia and the Himalaya by up to 2,350 km (14, 19, 20) (Fig. 1). In this paper, we will consider several possible explanations of the observed discrepancy and propose a tectonic scenario that can reconcile the disparate estimates and identify the structure(s) that accommodated the ‘missing’ convergence.

**Size of Greater India Through Time**

The only available technique to quantify past motions between continental blocks that are not connected through a passive margin to oceanic basins is paleomagnetism. A wealth of paleomagnetic data from the Ordovician, Triassic, and lower Cretaceous rocks of the Tibetan Himalaya consistently demonstrates minor net North–South (N-S) motion of the Tibetan Himalaya relative to India since these times (SI Text). The youngest rocks that demonstrate a relatively small Greater India are approximately 120 Ma old and show a net convergence between India and the Tibetan Himalaya of 2.1 ± 5.5°, or 233 ± 877 km (Fig. 2).

After adding the modern width of Greater India (i.e., the Himalaya, approximately 250 km N-S), these data suggest that Greater India in early Cretaceous time was not larger than approximately 900 km (SI Text). This conclusion is consistent with pre-Cretaceous Gondwana plate reconstructions (17, 27) as well as with the notion that the Paleozoic and older stratigraphies of the Himalayan zones are correlative, suggesting that during their deposition Greater India formed a contiguous continental margin (16, 24–26). By assuming that Greater India remained only several hundreds of kilometers wide until collision with Asia, Aitchison et al. (13, 28) demonstrated that the leading edge of Greater India would have passed the equator approximately 55 Ma ago, and suggested that the 55–50 Ma collision record (what is widely regarded as the Tibetan Himalaya–Asia collision) resulted from just the obduction of ophiolites onto the leading, Tibetan-Himalayan edge of Greater India. By also assuming negligible Cenozoic intra-Asian shortening, their model proposed that the India–Asia collision occurred at approximately 34 Ma. Paleomagnetic evidence from upper Cretaceous (approximately 68 Ma) and Paleocene (approximately 59 Ma) rocks from the Tibetan Himalaya (29–31) and cratonic India, however, demonstrate that during the late Cretaceous to Paleocene, the Tibetan Himalaya was separated by 22.0 ± 3.0° of latitude (2.442 ± 333 km N-S) from India (Fig. 2). These paleomagnetic data pass both fold and reversal paleomagnetic field tests at high confidence (SI Text), demonstrating their preexisting, primary magnetic acquisition. This much larger size of Greater India at the time of collision than during the early Cretaceous results in a paleomagnetically determined collision age of 48.6 ± 6.2 Ma (Fig. 2; SI Text), consistent with the 52 Ma age of first arrival of Lhasa-derived sediments in the Tibetan Himalaya (3). This large dimension of Greater India is also consistent with the position of the southern Asian margin at the time of collision based on restoration of intra-Asian deformation (14). Therefore, paleomagnetic data show that between 118 and 68 Ma, Greater India became extended and the Tibetan Himalaya drifted 24.1 ± 6.3° (2.675 ± 699 km N-S) northward relative to cratonic India (Fig. 2), followed by convergence of a similar magnitude after collision.

**Cretaceous Greater Indian N-S Extension**

Cretaceous extension within Greater India has previously been inferred from sedimentary facies changes in the Tibetan Himalaya (17, 18) and from lower Cretaceous (140–100 Ma) alkali-basaltic volcaniclastic sediments with a geochemistry interpreted to record intracontinental rifting (32, 33). The 2.675 ± 700 km of N-S extension between 118 and 68 Ma, inferred from paleomagnetic data (Fig. 2), requires minimum extension rates of 40–67 mm/yr. Such rates are typical for midoceanic ridges (pre-drift continental extension rates rarely exceed 20 mm/yr, ref. 34), and the magnitude of extension is an order of magnitude larger than that of typical extended continental margins (34). Thus, at least one oceanic basin—the Greater India Basin(s) (GIB)—must have formed between the Tibetan Himalaya and cratonic India.

![Fig. 1. Tectonic map of the India–Asia collision zone. Bars represent the amount of post-50 Ma India–Asia convergence, and the amount of intra-Asian (14), Himalayan (19, 20), and missing shortening along the collision zone. We calculated the Himalayan shortening deficit using a reconstruction of Asian deformation (14) embedded in global plate circuits (4, 34). Our maximum estimate of undocumented convergence uses (i) plate convergence estimates since 50 Ma, 3,600 ± 35 km for the eastern Himalayan syntaxis (4); (ii) approximately 600 km of shortening reconstructed in eastern Tibet since 50 Ma (14); and (iii) up to 650 km of shortening reconstructed from the eastern Himalaya (51), resulting in a 2,350 km deficit. Since approximately 25–20 Ma, the total amount of plate convergence is up to 1,300–1,000 km in the eastern Himalaya (4). Shortening since approximately 25 Ma in the Himalaya, along the main central thrust (MCT) and in the Lesser Himalaya (LH), is approximately 400–700 km (20), and in Tibet, approximately 200–300 km (14), leaving a modest shortening deficit of several hundreds of kilometers. We ascribe this deficit to uncertainties in the Tibet reconstruction, uncertainties in the timing of Tibetan Himalaya (TH) shortening, and the fact that balanced cross-sections provide minimum estimates. STD, South Tibetan Detachment; WYSZ, Indus–Yarlung Suture Zone; MBT, main boundary thrust.](https://www.pnas.org/content/10.1073/pnas.1117262109/f1)
India, separating a microcontinent from cratonic India (Fig. 3). The paleogeography of extended Greater India may have consisted of one or more deep basins alternating with (stretched) continental fragments, similar to Mediterranean paleogeography (35). The Cretaceous extension that would have opened the GIB (2,675 ± 699 km) encompasses the approximately 2,350 km of plate convergence that remains undocumented in the geological record of the Himalaya (Fig. 1). Numerical models demonstrate that continental lithosphere can subduct if its buoyant upper crust becomes decoupled from the subducting continent, but denser oceanic or thinned continental lithosphere can subduct without accretion (36). These modeling results are consistent with the observation that many convergent margins with oceanic subduction are nonaccreting (37). If 2,675 ± 699 km of extension created up to approximately 2,350 km of oceanic crust and highly extended continental margins in the GIB, subduction of that crust thus provides a straightforward explanation for the discrepancy between convergence and shortening.

Subduction History and Mantle Tomography

Subduction of the GIB following the approximately 50 Ma Tibet–Asia collision is consistent with seismic tomographic images of the mantle beneath India and Tibet. These images reveal three prominent velocity anomalies that have been interpreted as subducted Indian plate lithosphere (38–40) (Fig. 4). The deepest anomaly, at approximately 900 km and greater depth, is generally considered subducted Neotethyan oceanic lithosphere, detached sometime after the Tibetan Himalaya–Lhasa collision (38–40). A shallower anomaly between approximately 400- and 850-km depth would hence be Cenozoic in age (38–40); it projects directly below the reconstructed position of the Tibetan Himalaya between 50 and 25 Ma (Fig. 4). A third conspicuous body imaged horizontally below Tibet over a distance of approximately 500 km from the Himalayan front represents Indian continental lithosphere that has underthrust Asia since the last phase of slab break-off (39, 41). Taking Asian shortening (14) into account, this horizontal body represents the last 10–15 Ma of India–Asia convergence.

Seismic tomographic images also show anomalies in the lower mantle at equatorial latitudes (Fig. 4A), generally interpreted as a result of Cretaceous intraoceanic subduction (40, 42). Aitchison et al. (28) suggested that this anomaly resulted from intraoceanic subduction that terminated with ophiolite obduction onto the leading edge of Greater India. We agree that this anomaly represents the relict of an intraoceanic subduction zone, but we note that the much larger size of Greater India in late Cretaceous time shown by paleomagnetic data (Fig. 2) positions the northern margin of the Tibetan Himalaya above this equatorial lower mantle anomaly around 70 Ma, not 55 Ma (Figs. 3 and 4). This reconstruction is consistent with structural and stratigraphic evidence for ophiolite obduction onto the Tibetan Himalaya at approximately 70 Ma (5, 6).
Location of a Paleogene Subduction Zone Within the Himalaya

The collision between the Tibetan Himalayan microcontinent and Asia at approximately 50 Ma, and the subsequent closure of the Greater India Basin south of this microcontinent, requires a Paleogene to Miocene subduction zone south of (i.e., structurally below) the Tibetan Himalaya. The location of this subduction zone must be located somewhere within the modern Himalayan thrust belt, and therefore has implications for the interpretation of existing geological evidence on the contemporaneous evolution of the Himalaya (Fig. 3).

Since the onset of thrusting of the Greater Himalaya over the Lesser Himalaya along the Main Central thrust approximately 25–20 Ma ago, cumulative shortening in the Himalaya (19, 20) and Asia (14) is close to contemporaneous India–Asia convergence (4) (approximately 1,000 km). The continental clastic rocks of the Lesser Himalaya demonstrate continuous subduction of continental lithosphere and accretion of its upper crust to the Himalaya in this time interval. Thus, the discrepancy between predicted convergence and measured shortening is largely concentrated between 50 and approximately 25–20 Ma. Because the Tibetan Himalaya collided with Asia at or before approximately 50 Ma, and the deformation of the Lesser Himalaya is Miocene in age (43), 50–25 Ma convergence must have been accommodated structurally below (i.e., south of) the Tibetan, but above (i.e., north of) the Lesser Himalaya. As mentioned before, the total displacement along the Main Central thrust, as well as convergence accommodated within the Greater Himalaya, remains unknown due to severe Miocene deformation; however, well-dated prograde mineral growth and magmatism (21–23, 44) in the Greater Himalaya shows evidence for burial and heating between 45 and 25 Ma. If Cretaceous extension opened a single Greater Indian Ocean separating a microcontinent from India (Fig. 3), then these Paleogene metamorphic ages would suggest that the Greater and Tibetan Himalaya both belonged to a single microcontinent that collided with and accreted to Asia around 50 Ma. During the 50–25 Ma subduction of the Indian Plate (i.e., the GIB), the Greater and Tibetan Himalaya would then have thickened and metamorphosed as part of the compressed overriding plate (i.e., together with the Tibetan plateau to the north). Subduction—without accretion—would have been concentrated along a precursor of the Main Central thrust. If the GIB had a more complex paleogeography, then the Greater Himalaya could contain a ductile thrust stack (duplex) of deep marine rocks underplated and metamorphosed below the Tibetan Himalaya throughout the Paleogene. Pre-25-Ma prograde metamorphic ages in the Greater Himalaya vary considerably, from 45 Ma migmatitic rocks in gneiss domes in the Tibetan Himalaya (21) to 25 Ma eclogites in Nepal (23); these ages may represent the different times at which Greater Himalayan rocks were structurally buried in the duplex. In any case, the GIB suture lies either structurally within or below the Greater Himalaya.

Microcontinent–Continent Collision (50 Ma) and India–Asia Collision (25–20 Ma)

In our model, the approximately 50 Ma India–Asia collision represents collision of an extended microcontinental fragment (that contained the rocks now found in the Tibetan Himalaya) and continental Asia. This collision led to orogeny (14, 45), but was followed by ongoing oceanic subduction of the GIB. The hard continent–continent collision followed approximately 25 Ma later with the arrival of much less extended, contiguous continental Indian lithosphere to the collision zone, leading to increased coupling at the plate contact (46). Such increased coupling is consistent with (i) the similarity between shortening and convergence since 25–20 Ma; (ii) the onset of Greater Himalayan extrusion along the South Tibetan detachment and Main Central thrust (2); and (iii) the simultaneous and sudden onset of far-field
deformation into Central Asia (14) (e.g., deforming and uplifting the Tien Shan, ref. 47) (Fig. 1). Comparison of our plate and deformation reconstructions with seismic tomography suggests that this latter collision was followed by slab break-off at approximately 15–10 Ma and horizontal underthrusting of India below Tibet thereafter. The onset of this last phase of India–Asia collision is contemporaneous with a period of outward growth and extension of the Tibetan plateau (10, 12, 48).

The recognition of major Cretaceous extension in India and a multistage India–Asia collision history no longer requires models invoking major continental extrusion from Tibet predicting >2,000 km of Cenozoic intra-Asian convergence (10–12), but is consistent with kinematic and palaeomagnetic reconstructions showing <1,000 km of intra-Asian shortening (8, 14, 15, 49). Our model does not require younger initial collision ages (13) and is in line with geological data from the Indus–Yarlung suture zone (3), suggesting an approximately 50 Ma Tibetan Himalaya–Asia collision. It identifies the Greater Himalaya as the exhumed mid- to lower-continental crust that resided directly above a subduction zone from approximately 50 to 25 Ma. Finally, the hard collision was followed by a substantial increase in erosion rates within the Himalayan system, which may reflect a more vigorous South Asian monsoon (50), highlighting another potential link between geodynamic processes forming the Tibetan-Himalayan mountain belt and climate evolution.

Paleomagnetic Constraints on the Age of the India–Asia Collision and Size of Greater India. The relative positions of continents that are directly connected by ocean basins are determined by plate circuits based on marine magnetic anomalies and fracture zones (1). The paleolatitude of a continent is paleomagnetically determined from global synthetic apparent polar wander paths (APWPs), which are obtained by rotating all available high-quality paleomagnetic poles using Euler poles from the plate circuit to a chosen reference location (2, 3). This paper uses the most recent global synthetic APWP of Torsvik et al. (3), which covers the last 320 Ma. The global synthetic APWP (3) did not include the minor changes in the Indo-Atlantic plate circuit of van Hinsbergen et al. (4) used in our plate reconstruction. These changes, however, do not significantly influence the analyses below. From 320 to 440 Ma, the analysis below uses the APWPs for Gondwana and Laurasia of Torsvik and van der Voo (5), and before 440 Ma, uses the Gondwana poles from Torsvik et al. (6). These APWPs are determined for individual continents based on paleomagnetic poles of that continent alone.

The global synthetic APWPs do not include poles from continental blocks that are not bounded (or not anymore) by oceans, but are now instead separated by deformed belts, such as the northern edge of Greater India (i.e., the Himalaya) and the southern edge of Greater Asia (i.e., the Tibetan orogen). These blocks are frequently internally deformed by shortening and may have experienced regional and local vertical axis rotations during tectonism. Although paleomagnetic data from these deformed blocks cannot be used in APWP compilations, the inclination component can be used to calculate the paleolatitude of these blocks through time for comparison with plates in the plate circuit.

We assess the relative paleolatitude of the Indian and Siberian cratons that bound the India–Asia collision zone by using the APWPs described above to calculate the predicted paleolatitude of a reference location presently located on the Indus–Yarlung Suture Zone (IYSZ) for each continent (29°N, 88°E) (Table S1). We test the accuracy of these APWP predictions with paleolatitude of a reference location calculated from robust lava-based paleomagnetic poles from cratonic India. We then add paleomagnetic information from rocks directly bordering the IYSZ, that is, paleomagnetic poles determined from lavas and sediments from the Lhasa and Qiangtang blocks and the Tibetan Himalaya. The selection of poles from the Lhasa and Qiangtang blocks, the Tibetan Himalaya, and cratonic India are described below, with sampling localities shown in Fig. S1.

Paleomagnetic Data Procedures. A robust paleomagnetic pole is calculated from primary, well-determined, independent readings of the geomagnetic field over a time period that is long enough to average the effect of paleosecular variation of the geomagnetic field, but short enough so as not to integrate appreciable plate motion. It is generally assumed that continuous sections of sedimentary rocks average secular variation, such that a stratigraphic series of site mean directions, or a magnetostratigraphic column, will provide a good characterization of the magnetic field. This assumption is only valid, however, if the preserved magnetic directions (i) are primary and (ii) have not been biased by sedimentary inclination shallowing caused by particle settling and compaction (7, 8). When magnetic directions are collected at the site level (in contrast to a continuous stratigraphic succession in magnetostratigraphic studies), site mean directions must be of comparable reliability before they can be transformed to virtual geomagnetic poles (VGPs) to calculate the average paleomagnetic pole at a study location. In the compilations below, we apply the following filtering criteria to site mean directions determined from sedimentary rocks, by excluding sites that (i) are not used by the original authors, if reason for exclusion is provided; (ii) contain directions of mixed polarity (i.e., a single sample of the geomagnetic field (site mean direction) should be short enough to exclude a reversal event); (iii) are characterized by fewer than five samples; (iv) have $\alpha_{95}$ values (the radius of the 95% confidence interval on the mean direction) greater than 20°; (v) or deviate more than 45° from the locality mean direction.

Paleomagnetic results from lavas must be treated differently than results from sediments, because the processes and timescales by and over which magnetic directions are recorded are principally different. Several independent readings of the geomagnetic field are required to accurately characterize its time-averaged behavior, which is fundamental to determining a robust paleomagnetic pole. Cooling of a single, thin (1–3 m) lava unit will record a geologically instantaneous measurement of the geomagnetic field. Furthermore, subsequent lavas can extrude within a short time period (years), such that several stratigraphically successive lavas often record the same magnetic field direction, meaning that each lava unit may not provide an independent reading of the geomagnetic field. Hence, paleomagnetic data from volcanic units must first be filtered so that all site mean directions are of comparably high quality, and then, if the sampling strategy permits, stratigraphically successive site mean directions that are statistically indistinguishable should be combined into direction groups. In the compilations below, we apply the following filtering criteria to site mean directions determined from lavas by excluding sites that (i) are not used by the original authors, if reason for exclusion is provided; (ii) contain directions of mixed polarity; (iii) are characterized by fewer than five samples; (iv) have k values (Fisher’s precision parameter, ref. 9) less than 50; (v) or deviate more than 45° from the mean site mean direction.

This filtering procedure is commonly used by the geomagnetic field community (10, 11). The assignment of direction groups follows from the original authors of each of the studies described below, and in general follows the procedures described by Dupont-Nivet et al. (12) and Lippert et al. (13).

Paleomagnetic studies of the present and ancient magnetic field indicate that VGPs fit a Fisherian distribution better than the parent directions (11, 14). Therefore, we transform site mean and direction group directions into VGPs and calculate the Fisher mean VGP for each sampling locality. We evaluate the averaging of secular variation of a mean lava-based VGP by comparing the calculated dispersion (S) of VGPs to the dispersion observed in ancient lavas that yield good estimates of a geocentric axial dipole field when averaged (11, 14), and to the dispersion determined from paleosecular variation models (15). If the dispersion of the VGPs is consistent with dispersion observed in young lava successions, then we conclude that the sample set represents and has averaged secular variation.

We calculate the expected inclination and its uncertainty at the reference location on the IYSZ (29°N, 88°E), as well as the expected paleolatitude and corresponding uncertainty of the reference locality from each tilt-corrected locality paleomagnetic pole following Butler (16). Paleomagnetic poles, predicted inclinations, and paleolatitudes are listed in Table S1. All age assignments follow the original authors unless otherwise noted and are
keyed to the same timescales as used in the global synthetic APWP (3), that is, Gradstein et al. (17) and Cande and Kent (18), unless the section is dated using radiometric techniques.

**Paleomagnetic Poles Used in This Study.** Paleomagnetic poles from cratonic India. Two robust paleomagnetic poles from the Rajmahal (118 ± 1 Ma) and Deccan (65 ± 1 Ma) Traps on cratonic India are recalculated based on the most recent paleomagnetic data. These poles are used to test the accuracy of the global synthetic APWP (3) for predicting Indian paleolatitudes.

**The Deccan Traps.** The end-Cretaceous Deccan Traps in western India have been the focus of many paleomagnetic (see reviews by Vandamme et al., ref. 19, and Chenet et al. ref. 20) and geochronologic (see reviews by Hofmann et al., ref. 21, and Chenet et al., ref. 22) studies. High-precision chronologic (see reviews by Hofmann et al., ref. 21, and Chenet et al. ref. 20) and geo-

---

**Paleomagnetic Poles from Southern Tibet (Greater Asia).** Eocene-Oligocene lavas. Paleomagnetic data from well-dated upper Eocene-lower Oligocene (35 ± 3 Ma) basaltic lavas from the Qiangtang block are described by Lippert et al. (13). Thirty-three site mean directions from three sampling localities have been filtered and binned into 20 independent direction groups with a dispersion that is consistent with modern secular variation studies. These lavas yield a maximum likelihood estimate of paleolatitude of 28.7 ± 3.7°N at a present reference site at 33°N, 88°E on the Lhasa-Qiangtang suture. Because there has been negligible north-south-directed upper crustal shortening or rotation within the Lhasa block throughout the Neogene (29–31), we can transfer this paleolatitude directly to our reference position on the IYSZ, 4° of latitude to the south, resulting in a paleolatitude estimate for the reference location of 24.7 ± 3.8°N at approximately 35 ± 3 Ma.

**Paleogene lavas.** Basaltic to andesitic lavas, tuffs, and volcanoclastic units of the upper Paleocene to lower Eocene (56–47 Ma) Linizong formation (LZF) blanket a large area of the southern Lhasa block (32, 33). These volcanic units have been the focus of several paleomagnetic studies because of their potential to reveal the paleolatitude of the southern margin of Asia at approximately 56–47 Ma (Fig. S1) (34–39). Paleolatitude estimates for the reference location on the IYSZ from these individual studies range from approximately 12°N to as high as approximately 32°N, mainly as a result of the low number of independent site mean directions in each study.

We compiled 65 reliable data from the six studies of the upper LZF (i.e., Pana and upper Nianbo formations) listed above. After applying the data quality filter described above, excluding 37 of 89 reported lava site mean directions, the mean paleomagnetic pole in tilt-corrected coordinates is located at 80.1°N, 248.6°E (K = 26.8, A95 = 3.9°, S = 15.7°, n = 52). The 52 site mean directions used to calculate this filtered paleomagnetic pole include data from each of the six independent studies, pass a reversal test at 95% confidence (class C: Ycritical = 7.6°, Ycalculated = 10.9°; ref. 40), and pass a regional fold test at 95% and 99% confidence (X2 test of McFadden, ref. 41) (Table S7). Importantly, the calculated dispersion of this filtered VGP is consistent with known dispersion caused by paleostructural variation (11). We conclude that this paleopole more accurately characterizes the time-averaged behavior of the geomagnetic field than any previous individual study of the LZF. The 56–47 Ma paleolatitude of the reference site on the IYSZ predicted from this pole is 19.6 ± 3.9°N. Some recent studies (36) have reported reconnaissance paleomagnetic data from the lower LZF (approximately 64–60 Ma), suggesting paleolatitudes as low as 6.6°N ± 8.5°N (reference locality 30.0°N, 91.2°E). These anomalously low latitudes would imply unlikely large and fast northward motion (>1,500 km) of southern Tibet from 60 to 50 Ma, the evidence for which is either lacking or remains unrecognized. These results are based on a limited number of sites from which our data quality filter removes too many site mean directions to provide a statistically robust paleomagnetic pole. We therefore choose to not incorporate these data into our compilation.

**Upper Cretaceous redbeds, Maxiang.** Sun et al. (42) report paleomagnetic data from the 100–72 Ma Shexing formation of red beds that outcrop along the Lhasa-Golmud highway near Maxiang.
Site mean directions calculated from the high-temperature characteristic remanent magnetization (ChRM) component pass a fold test at high confidence. We evaluated the distribution of high-temperature specimen directions for inclination shallowing following the elongation/inclination (E/I) method of Tauxe and Kent (15). Samples with mean angular deviations of ChRM directions >15° and with reversed polarity ChRM directions were removed from the population to exclude poorly resolved or transitional directions. The Vandamme cutoff procedure for identifying outliers in the direction population (43) removed another seven samples, resulting in a mean direction of the Shexing formation with declination = 334.4°, inclination = 31.2° (χ95 = 2.8°, k = 26.7, n = 100) (Fig. S3A). We calculated a flattening factor of 0.66 (0.53 and 0.91 95% confidence interval), resulting in an E/I corrected inclination of 40.5° (33.3–47.7% 95% confidence interval) (Fig. S3 C and D). These results indicate approximately 9° of inclination shallowing in the fluvial-lacustrine redbeds of the Shexing formation, which is typical of these facies in Asia (12, 13). The formation mean direction calculated from the E/I-corrected directions is declination = 334.4°, inclination = 41.6°, χ95 = 2.8°, k = 26.0, n = 100 (Fig. S3F), with a corresponding pole at 74.1°N, 342.7°E (A95 = 2.3). The calculated paleolatitude for the reference location on the IYSZ is 23.8 ± 2.3°N at 100–72 Ma, which is consistent with E/I-corrected data from upper Cretaceous redbeds from the Penbo regions of the Lhasa terrane (see below).

**Upper Cretaceous redbeds, Penbo.** We use paleomagnetic data from the nonmarine Takena formation and calculations of a late Cretaceous (105–90 Ma, ref. 44) paleolatitude for the Lhasa Block of Tan et al. (34). The distribution of the sample directions from this dataset are consistent with inclination shallowing that is readily attributed to sedimentary depositional processes. These directions have been corrected by Tan et al. (34) using the E/I method (15). The paleomagnetic pole calculated from these tilt and inclination shallowing corrected sediments is located at 79.6°N, 329.9°E (A95 = 2.2). The paleolatitude of the reference location on the IYSZ in Lhasa-terrane coordinates calculated from this pole is 23.7 ± 2.2°N at approximately 105–90 Ma.

**Lower Cretaceous Lavas.** Paleomagnetic results from volcanic rocks of Cretaceous age have been reported in two recent studies. Sun et al. (45) describe 15 site mean directions from the 114.2 ± 1.1 Ma Woronggou formation rhyolites near Deqing, on the west shore of Nam Co (Table S8). Ten site mean directions have either too few samples defining the site mean direction or precision parameters <50, leaving only five directions for further analysis. Chen et al. (46) describe 19 site mean directions from 130–110 Ma tuffs and lavas of the Zenong Group near the town of Cuoqin in the central Lhasa terrane (Table S8). Nine of these site mean directions have precision parameters <50°, and another direction is considered an outlier by the original authors, leaving only nine site mean directions to describe the geomagnetic field at this locality. We combine the filtered results of Sun et al. (45) and Chen et al. (46) to calculate a lava-based paleomagnetic pole for the Lower Cretaceous of the Lhasa terrane. Although both localities show similar inclinations, the declinations vary by approximately 30–40°, indicating significant rotations between the localities (Fig. S4). We follow Doubrovine and Tarduno (24) and Lippert et al. (15), and calculate a maximum likelihood virtual geomagnetic latitude (VGL) using the Arason and Levi method (47). First, we calculate the VGP’s for the filtered site mean directions and then calculate the VGL of the reference site on the IYSZ. These VGLs are then used as input to calculate the maximum likelihood latitude for the reference site from these data: 16.2 ± 3.6°N at approximately 130–110 Ma. We note, however, that the dispersion of these VGLs is only 7°, indicating that paleosecular variation has been undersampled by these igneous units, and that this paleolatitude estimate may not be robust. Additional paleomagnetic studies focusing on Cretaceous volcanic rocks from the Lhasa terrane are clearly warranted.

**Upper Cretaceous–upper Paleocene marine sediments.** Paleomagnetic data from the Maastrichtian to Paleocene Zongshan and Selandian-Thanetian Zongpu formations near Gamba and Duela in Southern Tibet are described by Patzelt et al. (59) and Yi et al. (52). Both datasets pass paleomagnetic fold tests and reversal tests at high confidence as described in the original studies, consistent with a primary magnetization. Dupont-Nivet et al. (12) tested the sediment-based data of Patzelt et al. (59) using the E/I procedure and found only minor (<5°) amounts of inclination shallowing, as common for marine limestones. Yi et al. (52) also evaluated their data using the E/I procedure and also found minor (4.4°) inclination shallowing. Here we combine the ChRM specimen directions of Patzelt et al. (59) and Yi et al. (52) from
the Zongpu formation to recalculate the magnitude of inclination shallowing. Tilt-corrected outlier directions in this combined dataset were removed using the Vandamme cutoff criteria (43), resulting in 245 individual directions that define a slightly elongated distribution (Fig. S6A). This filtered dataset passes a reversals test at high confidence ($Y = 2.4^o$, $Y_c = 12.0^o$, class C) (40). We calculated a flattening factor of 0.69 (0.61% and 0.80 95% confidence interval), resulting in an E/I-corrected inclination of 15.6° (12.6–18.5° 95% confidence interval) (Fig. S6 C and D). These results indicate approximately 4° of inclination shallowing in the marine limestones of the Zongpu formation.

Two outlier directions were removed from the population of E/I-corrected directions, resulting in a formation mean direction of declination = 358.6°, inclination = 15.5°, $\alpha^95 = 2.3^o$, $k = 16.6$, $n = 243$ (Fig. S6B). The corresponding poles for the Zongpu formation calculated from this direction, as well as the for the Zongshan formation previously calculated by Dupont-Nivet et al. (12) are shown in Table S1. We calculate a paleolatitude for the reference location on the IYSZ of $8.7\pm1.7^\circ$N with an age range of 62–55 Ma, and $-5.0\pm2.8^\circ$N for 71–65 Ma (12). The age of the Zongpu formation latitude is constrained by recent magnetostratigraphy (52). The upper Cretaceous pole is rotated east of the Indian APWP, however, and the rotation-corrected paleolatitude at 71-65 Ma is $-4.9\pm2.8^\circ$N. Compared to the Indian APWP, the Zongpu pole ($59\pm3^o$ Ma) shows $16.6\pm2.9^o$ of latitudinal distance between India and the Tibetan Himalaya, whereas the Zongshan pole ($68\pm3^o$ Ma) indicates $13.6\pm4.4^o$ of latitudinal separation. (Fig. 2 and Figs. S2 and S5) (12).

Cretaceous volcaniclastic sediments. Klootwijk and Bingham (58) sampled the Barremian to late Albian ($127-112$ Ma) Dzong formation in the Thakkhola graben. Ninety-five paleomagnetic samples from the lower glauconitic sandstone part of the formation, which has been assigned an Aptian age (121–112 Ma) (60), pass a paleomagnetic fold test at high confidence (58). These data were used to calculate a paleomagnetic pole located at $-12.0^\circ$N, $108.6^\circ$E ($\alpha^95 = 3.7^o$). This pole is located east of the coeval Indian APWP pole, indicating significant rotation of the Tibetan Himalaya with respect to cratonic India sometime after the deposition of the Dzong formation. The rotation-corrected paleolatitude is $-45.1\pm3.7^o$; for comparison, the uncorrected paleolatitude is $-44.4\pm3.7^o$N. Both of these estimates overlap within error with the coeval Indian APWP pole and the cratonic India pole from the Rajmahal Traps. Notably, the paleolatitude difference between rotation-corrected Dzong pole calculation and the Rajmahal pole prediction is $-2.1\pm5.5^o$ of latitude.

Triassic marine sediments. Paleomagnetic data from Triassic strata throughout the Tibetan Himalaya were collected from several published sources (Fig. S1 and Table S9). Stratigraphic nomenclature follows the original authors, whereas stage assignments follow Garzoni (60), and stage ages follow Gradstein et al. (17).

Klootwijk et al. (61) describe paleomagnetic results from six sampling localities from Kashmir in the western Tibetan Himalaya. Sampled lithologies include marine limestone, shales, and sandstones of lowest Induan to Norian age (i.e., 248.2–209.6 Ma). Most samples revealed high-temperature ChRM interpreted as primary in tilt-corrected coordinates. The mean VGP calculated from these six localities gives a paleolatitude of $-55.2\pm8.7^o$N for the reference location on the IYSZ. The Kashmir pole shows a large rotation from the Indian APWP. The rotation-corrected paleolatitude for the reference location is $-49.6\pm8.7^o$N.

Induan to early Norian (248.2–215 Ma) greenschist-facies meta-shales and limestones of the Tamba and Mukut formations of the western Dolpo region of the Tibetan Himalaya record a high-temperature magnetization carried by magnetite and interpreted to be prefolding in age (62). Ten of the 26 site mean directions meet our quality criteria. A new paleomagnetic pole calculated from the 10 corresponding VGPs is located at $-2.9^\circ$N, $281.4^\circ$E ($\alpha^95 = 18.5^o$, $K = 7.8$), but is located east of the Indian APWP. The rotation-corrected paleolatitude for the reference location is $-55.9\pm18.5^o$N. This paleolatitude is the most southerly in this compilation, lying more than 25° of latitude south of the APWP prediction. According to this pole, the Tibetan Himalaya (TH) was derived from the center of the Indian craton; this is geologically implausible. We choose to exclude these Dolpo results from our compilation given the large number of sites rejected, the low number of samples, the greenschist-facies metamorphism of the limestones, and the weak fold test used to suggest a primary magnetization. Future paleomagnetic sampling of Triassic and younger rocks in the Dolpo region are needed to verify these results.

Paleomagnetic results from two sampling localities in the Ladinian to Norian (234.3–209.6 Ma) Thinigaon Limestone of the Thakkhola region are described by Klootwijk and Bingham (58). A high-temperature ChRM is resolved in most samples and is interpreted to be primary in tilt-corrected coordinates. The mean VGPs calculated from these two localities show only small rotation with respect to India. The rotation-corrected paleolatitude estimates for the reference location are $-30.1\pm5.7^o$N and $-26.9\pm10.0^o$N.

Lower Anisian to lower Norian (241.7–215 Ma) carbonates from a single sampling locality near the Manang area of the Tibetan Himalaya record a ChRM carried by magnetite (63). A positive fold test of the ChRMs suggests that these directions are primary and suitable for calculating a paleomagnetic pole. This pole shows only minor rotation of the Manang region with respect to cratonic India since the Triassic. The rotation-corrected paleolatitude of the reference location is $-36.2\pm4.2^o$N.

Thirty-four paleomagnetic sampling sites collected from the lowest Induan to Norian (248.2–209.6 Ma) limestones of the Tamba Kurkur and Mukut formations of Central Nepal are described by Schill et al. (64). A high-temperature component carried by magnetite was interpreted as primary by these authors. Thirteen of these site mean directions meet our quality criteria, resulting in a mean VGP located at $14.1^\circ$N, $256.3^\circ$E ($\alpha^95 = 10.8^o$, $K = 15.7$). This pole is rotated east of the coeval Indian APWP. The rotation-corrected paleolatitude of the reference location is $-47.5\pm10.8^o$N.

In summary, paleomagnetic data from several different packages of Triassic rocks distributed throughout the Tibetan Himalaya record stable, primary remanences. The paleomagnetic poles from each of the sampling locations indicate differential amounts of vertical axis rotation with respect to cratonic India. We use the rotation-corrected paleolatitudes from each of the studies (excluding the results from Dolpo) described above to calculate the maximum likelihood paleolatitude (47) of the reference site in a Tibetan Himalaya reference frame of $-38.6\pm9.9^o$N. In contrast, the maximum likelihood estimate of the reference location calculated from the 250–200 Ma Indian APWP poles is $-30.1\pm6.9^o$N (the paleolatitude calculated from the Fisher mean of the 250–200 Ma Indian APWP poles is $-29.9\pm7.3^o$N). Thus, we find that the mean latitudinal separation between the reference location in a Tibetan Himalaya and cratonic India reference frame during the Triassic is $-9.0\pm10.6^o$ (Fig. S5). We note that several individual poles of high quality lie closer to the Triassic APWP poles than indicated by this comparison of the maximum likelihood estimates.

Ordovician red beds. Paleomagnetic data from the Shian formation of the Tibetan Himalaya near Spiti, Northwest India are described by Torsvik et al. (6), who assigned an Ordovician (500–450 Ma) age to these rocks. High-temperature ChRM
directions carried by hematite pass a fold test at high confidence, and the six paleomagnetic sampling sites yield a mean VGP located at $-20.4^\circ$N, $210.0^\circ$E ($\phi_{eq} = 13.4^\circ$, $\alpha = 26.0^\circ$) (Tables S1 and S10), which is rotated away from the coeval part of the Indian APWP. The paleolatitude of the reference location calculated from the rotation-corrected pole is $-37.7 \pm 13.4^\circ$N.

Implications of Paleomagnetic Data for the India-Asia Collision History. Age of the Tibetan Himalaya-Lhasa collision. The paleolatitude separation between the late Cretaceous and Paleocene poles for the TH and the coeval Indian APWP poles is remarkably similar (23.6 $\pm$ 3.7$^\circ$ at 59 Ma; 20.4 $\pm$ 4.8$^\circ$ at 68 Ma, using the trend of the Indian APWP adjusted to the Deccan Traps paleopole), suggesting that over this time span, the Tibetan Himalaya drifted northward at a similar rate as cratonic India (Fig. 2 and Figs. S2 and S5). We use these paleolatitude separation values to calculate a mean latitudinal separation between the Tibetan Himalaya and cratonic India of 22.0 $\pm$ 3.0$^\circ$ from 65 to 59 Ma (Fig. S5). In other words, paleomagnetism shows that sometime after 59 Ma, 22.0 $\pm$ 3.0$^\circ$ of North-South (N-S) convergence occurred between the northernmost exposed tip of the Tibetan Himalaya, located at the modern suture zone, and continental India.

If we assume that there was no convergence accommodated within Greater India prior to collision with Eurasia, we can calculate a collision age by constructing a Tibetan Himalayan “APWP” (or better, paleolatitude curve, Fig. S2) that is parallel to the Indian APWP and is projected forward in time until it intersects with the Asian paleolatitude curve (specifically, the paleolatitude calculated from the Linzingzong formation); the 95% uncertainty in latitude assigned to the Tibetan Himalayan APWP is $\pm 3^\circ$. The latitude of the northern Tibetan Himalaya overlapped with the latitude of the southern margin of the Lhasa block at 48.6 $\pm$ 6.2 Ma at 19.6 $\pm 3.9^\circ$N (95% confidence intervals, see Fig. 2 and Fig. S2).

Paleolatitude drift of the Tibetan Himalaya relative to continental India. Paleolatitudes calculated from paleomagnetic data from Orдовиcian, Triassic, and lower Cretaceous sediments of the Tibetan Himalayan sequence all overlap within error with paleolatitudes predicted from coeval cratonic Indian reference poles (Figs. S2 and S5). This overlap means that the N-S area of 22.0 $\pm$ 3.0$^\circ$ that disappeared due to convergence within Greater India sometime after 59 Ma (probably after 48.6 $\pm$ 6.2 Ma, see above) must have been created by extension after approximately 120 Ma.

When making a direct comparison between the paleolatitude of the Rajmahal Traps (118 $\pm$ 1 Ma) and the Dzong formation of the Tibetan Himalaya (121–112 Ma) a statistically indistinguishable post-118 Ma net separation of $-2.1 \pm 5.5^\circ$ of latitude ($-233 \pm 877$ km N-S separation) is obtained. This value shows that the Greater India 118 Ma ago was not more than 644 km (i.e., 877–233 km) larger than today. Today’s width of Greater India is equal to the width of the Himalaya—i.e., approximately 250 km. Hence, paleomagnetism constrains the maximum width (within 95% error bars) of Greater India 118 Ma ago at approximately 900 km. Using the 22.0 $\pm$ 3.0$^\circ$ of post-59 Ma convergence calculated above, the net increase in paleolatitudinal separation (i.e., the amount of N-S extension) between the Tibetan Himalaya and cratonic India implied by these direct comparisons is $24.0 \pm 6.3^\circ$ ($2.675 \pm 699$ km N-S) between 118 and 68 Ma.

The estimated size of the Greater India Basin will be refined by future studies that provide robust paleomagnetic poles from Cretaceous rocks of the Tibetan Himalaya. Nevertheless, reviewing the current state-of-the-art of published, robust paleomagnetic data from India, the Tibetan Himalaya, and the Lhasa terrane indicates that the Tibetan Himalaya must have drifted away from cratonic India during the Cretaceous, leaving in its wake a basin or several basins that accommodated a cumulative N-S extension of 2,675 $\pm$ 699 km.

Fig. S1. Location map of paleomagnetic studies listed in Table S1.
Fig. S2. Paleolatitudes of a reference site (29°N, 88°E) located on the present-day position of the Indus–Yarlung Suture Zone in Eurasian, Greater Asian, Tibetan Himalayan, and Indian reference frames. Numbers correspond to paleomagnetic poles described and listed in Table S1. Pl, Pliocene; Mio, Miocene; Oligo, Oligocene; Paleo., Paleocene; Jr, Jurassic; Tr, Triassic; P, Permian; Carb., Carboniferous; Dev., Devonian; Sil., Silurian; Ord, Ordovician; C, Cambrian; MCT, main central thrust; STD, South Tibetan detachment. Uncertainties in age are assigned based on the age of the units determined from either radiometric dates or geologic stages (17, 18), whereas latitude uncertainties are at the 95% confidence level. Question mark next to estimate 7 indicates that this pole may not fully average paleosecular variation.

Fig. S3. E/I correction (15) of high-temperature, primary magnetic component of the Shexing formation red beds at Maxiang, south, central Lhasa terrane (42). (A) Equal area plot of original paleomagnetic directions in tilt-corrected coordinates, with a mean inclination of 31.2° (magenta star, 95% confidence interval indicated in pink). Slight horizontal elongation of the direction distribution is consistent with sedimentary inclination shallowing. (B) E/I-corrected paleomagnetic directions after accounting for a flattening factor of 0.66. The E/I-corrected inclination is 41.6°. (C) Plot of elongation versus inclination for the TK03.geocentric axial dipole (GAD) paleosecular variation model (solid green line, ref. 15) and for the Shexing formation directions (barbed red line) for different flattening factors, f. Yellow lines are the results from 20 boot-strapped datasets. The crossing points of the Shexing formation and boot-strapped dataset with the TK03.GAD results represents the elongation/inclination pairs that are most consistent with the TK03. GAD field model. (D) Histogram of crossing points from 5,000 boot-strapped datasets. The most frequent flattening factor is f = 0.66, resulting in the distribution of directions shown in B.
Fig. S4. Equal area plot of site mean directions from lower Cretaceous volcanic rocks from the central and western Lhasa terrane that pass our data quality criteria (45, 46). Downward (upward) pointing directions are shown as filled (open) symbols. Star indicates the present dipole magnetic field direction. Significant improvement in the clustering of inclinations from in situ coordinates (A) to tilt-corrected coordinates (B) is consistent with a prefolding magnetization. The noticeably different declination values observed in the two localities are consistent with differential vertical axis rotation because the emplacement of these lavas and justifies the use of latitude-only paleolatitude methods (SI Text).

Fig. S5. Rotation-corrected paleomagnetic poles for the Tibetan Himalaya showing latitudinal separation between the Tibetan Himalaya and cratonic India for the (A) Paleocene, (B) latest Cretaceous, (C) early Cretaceous, and (D) Triassic. Ninety-five percent confidence limits of the pole positions are also shown.
Fig. S6. E/I correction (15) of high-temperature, primary magnetic component of the Zongpu formation marine limestones at Gamba and Duela, southern Tibetan Himalaya (52, 59). Format of figures follows Figs. S3 and S4. (A) Distribution of 245 original paleomagnetic directions in tilt-corrected coordinates, with a mean inclination of 11.2°. Horizontal elongation of the direction distribution is consistent with sedimentary inclination shallowing. (B) E/I-corrected paleomagnetic directions after accounting for a flattening factor of 0.69 (C and D). The E/I-corrected inclination is 15.5°, indicating that inclination shallowing in these marine limestones is <5°.
